ABSTRACT

We describe the calibration status and data products pertaining to the GR2 and GR3 data releases of the Galaxy Evolution Explorer (GALEX). These releases have identical pipeline calibrations that are significantly improved over the GR1 data release. GALEX continues to survey the sky in the Far Ultraviolet (FUV, ~ 154 nm) and Near Ultraviolet (NUV, ~ 232 nm) bands, providing simultaneous imaging with a pair of photon counting, microchannel plate, delay line readout detectors. These 1.25° field-of-view detectors are well-suited to ultraviolet observations because of their excellent red rejection and negligible background. A dithered mode of observing and photon list output pose complex requirements on the data processing pipeline, entangling detector calibrations and aspect reconstruction algorithms. Recent improvements have achieved photometric repeatability of 0.05 and 0.03 m_{AB} in the FUV and NUV, respectively. We have detected a long term drift of order 1% FUV and 6% NUV over the mission. Astrometric precision is of order $0.5''$ RMS in both bands. In this paper we provide the GALEX user with a broad overview of the calibration issues likely to be confronted in the current release. Improvements are likely as the GALEX mission continues into an extended phase with a healthy instrument, no consumables, and increased opportunities for guest investigations.

Subject headings: space vehicles: instruments — surveys — telescopes — ultraviolet: general

1. INTRODUCTION

We describe the calibration status and data products pertaining to the combined GR2 and GR3 data releases of the Galaxy Evolution Explorer (GALEX). GALEX is a NASA Small Explorer mission performing an all-sky ultraviolet (UV) survey in the Far UV (FUV ~ 154 nm) and Near UV (NUV ~ 232 nm) bands with $4 - 6''$ resolution and ~ 50 cm² effective area. At the time of this writing, over 13500 square degrees of this survey are available to the public via the Internet from the Multimission Archive at Space Telescope Science Institute (MAST).¹¹

The GR2 and GR3 releases have identical pipeline calibrations that are significantly improved over the previous GR1 release. Photometric precision at a given epoch is 0.05 and 0.03 m_{AB} in the FUV and NUV respectively. We have detected a long term drift of order 1% FUV and 6% NUV over the mission. The astrometric precision has

been improved to $0.5''$ RMS.

The path from raw telemetry to corrected catalogs, images and spectra is a complicated one for the GALEX pipeline. This fact is illustrated by Fig. 1, which shows a GALEX image in detector and sky coordinates, which are representative of the pre- and post-pipeline images. This overview highlights the data quality, errors and peculiarities that are likely to confront astronomers. As is true for any large dataset, knowledge of these basic characteristics is essential to avoid confusion.

The GALEX mission continues into an extended phase with a healthy instrument, no consumables, and increased opportunities for guest investigations. While the survey is on-going, it is likely that we will make improvements to the calibration and discover additional sources of error. We expect to provide updates to this paper on the web at WWW.GALEX.CALTECH.EDU, as well as in the literature.

This paper is organized as follows. In Section 2 we summarize the design of the mission and instrument. In Section 3 we describe how GALEX data are reconstructed and what the key pipeline products are. In Section 4 we describe the photometric calibration of the data, including a discussion of saturation effects and drift. In Section 5 we describe the instrument resolution across the field of view and as a function of detector gain. In Section 6 we describe the astrometric performance of the instrument. In Section 7 we describe the spectroscopy calibration and present an example extraction. Finally, in Section 8 we summarize the key points of the paper.

2. MISSION AND INSTRUMENT OVERVIEW

12:00 UT from the Kennedy Space Center into a circular, 700 km, 29° inclination orbit. This 0.5 m diameter instrument has a very wide 1.25° field of view sensitive to $m_{AB} \sim 21$ in the All Sky Imaging Survey (AIS), and to $m_{AB} \sim 25$ in the Deep Imaging Survey (DIS). The instrument provides simultaneous FUV and NUV imaging with a pair of photon counting, microchannel plate, delay line readout detectors. These detectors are well-suited to ultraviolet observations because of their excellent red rejection and negligible background. An objective grism mode is also available for low resolution spectroscopy. The last comparable survey in this wavelength range, which extended to $m_{AB} \sim 9$ was performed by the Belgian/UK Ultraviolet Sky Survey Telescope on the TD1 satellite launched in 1972 and described by Boksenberg et al. (1973).

GALEX makes science observations on the night side of each orbit (to keep sky background to a minimum) during “eclipses” that are typically in the range of 1500 – 1800 s. In the AIS, as many as 12 targets are observed during an eclipse, while the Medium Imaging Survey (MIS) has one target per eclipse and the DIS returns to the same target for 30 or more eclipses. As of this writing, we have observed over 19,000 square degrees of sky and accumulated over 4 terabytes of science telemetry. An overview of key performance parameters is presented in Tab. 1.

A GALEX detector head is shown schematically in Fig. 2. Individual photons incident at the cathode set off an isolated avalanche of current inside parallel 10-12 micron diameter microchannel plate (MCP) pores as they accelerate through a few-keV field. The resulting charge cloud at the rear of the MCP stack, approximately 10^7 electrons in size, is deposited on a double-layer anode, divided, and finally measured at each of four outputs. The layers of the anode form a pair of orthogonal delay lines. Timing differences measured for the charge pulses at each corner of the anode are proportional to the position of the initiating photon event. For faint UV observations, the combination of low background (zero read noise) and

FIG. 2.— GALEX sealed tube detector head electro-mechanical block diagram. The NUV and FUV tube heads are nearly identical with the principal differences being the choice of photocathode material (CsI for FUV and Cs_2Te for NUV) and window material (MgF_2 for FUV, SiO_2 for NUV). Also, the cathode material is deposited on the detector window in the NUV channel but directly on the MCP in the FUV channel. Instead of a cathode, the FUV window has a charged grid of wires that enhances the sensitivity of the detector. The NUV cathode is proximity focused on the front MCP, and due to its reentrant design is more prone to reflections from off-field sources. HV_{in} represents the negative applied voltage, 5-6 keV, while a resistor chain ($R_{gap} \sim 10$ MOhm in series with the MCPs at about 30 MOhm each) sets the voltage across the gap ($V_{gap} \sim 500$ V) and MCP stack ($V_{MCP} \sim 4500$ V) driving a detector bias current $I_{MCP} \sim 50 \mu\text{A}$. The detector pulse outputs in one dimension are labeled START and STOP (or sometimes “A” and “C”).

high red rejection that these detectors possess represents a favorable trade-off against the superior QE and field flatness of more conventional CCD detectors. Furthermore, MCP detectors do not require cooling, an important consideration in the contamination-sensitive UV band. In order to improve photometric performance, observations are dithered in a spiral pattern approximately 1’ in diameter (at a rate of approximately 0.5 revolutions per minute) that smooth out small scale variations in the flat field and reduce bright source fatigue on the MCPs.

A more detailed instrument overview is provided in Morrissey et al. (2005), while the mission design is described by Martin et al. (2005). Further details of our mission operations experience are described in Forster et al. (2006) and Morrissey (2006).

TABLE 1
SUMMARY OF MEASURED PERFORMANCE PARAMETERS FOR GALEX.

Item	FUV Band	NUV Band
Bandwidth: ^a	1344 – 1786 Å	1771 – 2831 Å
Effective wavelength (λ_{eff}): ^b	1538.6 Å	2315.7 Å
Mean effective area:	19.6 cm ²	33.6 cm ²
Peak effective area:	36.8 cm ² at 1480 Å	61.7 cm ² at 2200 Å
Astrometry (1σ , $R \leq 0.6^\circ$):	$\pm 0.59''$	$\pm 0.49''$
Field of view:	1.27°	1.25°
Photometry (1σ):	$\pm 0.05 m_{AB}$	$\pm 0.03 m_{AB}$
Zero point (m_{0UV}):	18.82	20.08
Image resolution (FWHM):	4.2''	5.3''
Spectral resolution ($\lambda/\Delta\lambda$):	200	118
Spectral dispersion	1.64 Å-arcsec ⁻¹	4.04 Å-arcsec ⁻¹
Detector background (typical):		
Total:	78 c-s ⁻¹	193 c-s ⁻¹
Diffuse:	0.66 c-s ⁻¹ -cm ⁻²	1.82 c-s ⁻¹ -cm ⁻²
Hotspots:	47 c-s ⁻¹	107 c-s ⁻¹
Sky background (typical): ^c	1000 c-s ⁻¹	10000 c-s ⁻¹
Limiting magnitude (5σ):		
AIS (100 s):	19.9	20.8
MIS (1500 s):	22.6	22.7
DIS (30000 s):	24.8	24.4
Linearity:		
Global (10% roll off):	18000 c-s ⁻¹	
Global (50% roll off):	91000 c-s ⁻¹	
Local (10% roll off): ^e	114 c-s ⁻¹	303 c-s ⁻¹
Pipeline image format:	3840 × 3840 elements with 1.5'' pixels	

^aIncludes wavelengths with effective area at least 10% of the peak value.

^bWavelength-weighted: $\lambda_{eff} = \frac{\int A_{eff} \times \lambda}{\int A_{eff}}$

^cThese correspond to 246 and 601 photons-s⁻¹-cm⁻²-sr⁻¹-Å⁻¹, respectively.

^dThese are worst-case values for point sources.

3. IMAGE RECONSTRUCTION OVERVIEW

The GALEX detector output is a list of time-ordered 40-bit photon positions and pulse heights. These data are delivered to the instrument Data Processing Unit (DPU), which adds a timing stamp every 5 ms (or every 20 μ s in uncompressed mode). The time stamp is derived from the spacecraft clock, which has a drift of the order of 1 s each week that is corrected with ground updates. Data are stored in the 2.8 GB ring buffer of a Solid State Recorder (SSR), which is down-linked to a ground station approximately four times each day.

The ground pipeline reconstructs a list of photon positions and arrival times into an image. Broadly speaking, the photon lists are corrected for detector effects and image motion, projected into sky coordinates, binned into images, flat fielded, and finally background subtracted. These final image products are then scanned by the open-source SExtractor program (Bertin and Arnouts 1995) to produce catalogs of source positions and fluxes. The steps along this path are described in more detail in the following sections.

3.1. Static Calibration

The static calibrations are those used to assemble raw detector event positions into accurate locations in the GALEX focal plane. They also flag events that are not photon generated, such as the periodic "STIM" pulses that are always electronically superimposed (in parallel with real photon events) on the detector anodes, and regions on the MCPs that are dominated by hotspots.

Each photon event in the GALEX science telemetry is a heavily encoded group of fields that, when decoded

TABLE 2
KEY DATA CONTAINED IN THE GALEX RAW6 FORMAT PHOTON LISTS. PHOTONS FROM THE DETECTOR ITSELF ARE NOT TIME STAMPED BUT RATHER TIME ORDERED, AND THE TIME STAMP IS ADDED BY THE DPU BEFORE BEING WRITTEN TO THE SSR.

Column	Bits	Description
t	40	Event detection time ^a
X_{AmC}	12	Raw X detector position in FEE pixels
Y_{AmC}	12	Raw Y detector position in FEE pixels
X_A	5	Wiggle (the phase of the TAC)
X_B	3	X axis coarse clock
Y_B	3	Y axis coarse clock
Q	5	Detected pulse height

^aIn high resolution mode, the timing precision uses 40 bits to attain 20 μ s resolution, however this mode is rarely used. For most data, only 32 bits are significant, attaining 5 ms resolution.

and assembled, produces key values listed in Tab. 2. In the GALEX design (Jelinsky et al 2003), a free-running coarse clock subdivides the large detector areas into an 8×8 grid. Detector event pulses are measured asynchronously while this clock runs, so that each position (proportional to the measured arrival time difference of pulses from either side of the delay line anode on each axis) comprises an integer number of coarse clock steps plus a fine position (essentially the coarse clock phase).

In order to construct a raw source position (X, Y) from these data, one would apply the following formulas:

$$X = X_{AmC} + \alpha X_B \quad (1)$$

$$Y = Y_{AmC} + \beta Y_B, \quad (2)$$

where the constants α and β are in the range of 2000 (solved by minimizing source widths across the field of view), X_B and Y_B are the coarse clock counters, and X_{AmC} and Y_{AmC} are the "fine" position measurements representing the coarse clock phase.¹² After the detector positions are assembled, the following static corrections are applied (in order) to correct the raw positions to a linear representation of the actual source position in the focal plane:

- **Centering and scaling:** Coarsely scales the raw positions from bins to microns. The scale factors are different for each axis.
- **Wiggle:** The GALEX coarse-bit sub-array approach allows degenerate combinations of coarse and fine components for a given detector location. Each of these may have a slightly different electronic non-linearity correction owing to the differing phases of the time-to-amplitude converter (TAC) for each event. The image of a single point source on the detector is thus *blurred* by the superposition of all of the TAC data, an effect referred to as wiggle. This contrasts with smaller, more conventional time-to-amplitude conversion systems. These do not utilize a coarse counter bit and translate all electronic non-linearities into source *position* errors rather than source *widths*. With careful part selection, "wiggle" in the flight units has been minimized considerably. In order to eliminate it completely, each detected event includes a 5-bit value X_A , which represents where in the TAC range each measurement was made. Residual electronic non-linearities are then removed using lookup tables for combinations of (X, X_A) and (Y, X_A) . Both axes use the same X_A data because the X and Y pulses are correlated in time for a given detector position.
- **Walk:** This transformation corrects position-vs-pulse-height (Q) errors. A lookup table correction applied in a similar manner as wiggle, reflective of the fact that the electronics can not perfectly compensate for pulse sizes that vary by a factor of 10 across the detector.
- **Spatial non-linearity (distortion):** A lookup table corrects high voltage detector edge effects, which cause electrons to bend from their optimal path, distorting the image especially near the edge of the field.
- **Hotspot masking:** Each detector has numerous small, high count rate features resulting from a combination of microscopic MCP debris and channel defects that combined generate about half of the intrinsic detector background. These spots come and go, and are best handled by direct masking, which eliminates only about a percent of the detector area. New masks are generated roughly

annually; hotspots are generally easy to pick out of images because they "reverse dither" (since they are fixed in detector space) and create $\sim 1'$ circular artifacts in GALEX sky-space images. In the data pipeline, the hot spot masks create localized regions of zero effective sensitivity in detector space, one reason why dithered observations are preferred for these detectors. Depending on pointing accuracy in a given observation, the dither typically maps these regions into "donuts" of reduced (but not zero) response on the sky.

3.2. Dynamic Aspect Correction

The fully-corrected event positions in spacecraft coordinates accurately record where each photon landed in the GALEX focal plane. The next step is to reconstruct the spacecraft pointing on the sky as a function of time in order to remove the dither pattern from the observed data. This is the 3-parameter "aspect," which includes the right ascension, declination, and roll of the telescope boresight. For imaging mode data, a precise estimate is arrived at by refining the spacecraft Attitude Control System (ACS) pointing estimate with NUV data¹³ binned into 1 s slices. These snapshot images are each matched to the ACT catalog (Urban et al. 1998) of known stars,¹⁴ and the average error vector from the matches to the catalog stars are used to establish a correction to apply to the ACS estimate. The source positions are then transformed to sky coordinates (J2000) using a Gnomonic projection based on the pointing at the interpolated time.

Grism data undergoes a similar process, but the software can not match spectra to known stars at this stage of processing. A relative aspect solution is performed based solely on the instantaneous spectral image positions, and astrometric refinement is added at a later stage.

Once sky coordinates have been assigned to each photon, an "extended photon list" is computed for internal use by the pipeline in forming the final data products. In cases where detailed, time-dependent behavior of one or more objects over the course of an exposure is of interest, the extended photon list can be written out to a so called "x-file," by special request.

3.3. Pipeline Products

Images and catalogs from various stages of pipeline processing reveal many characteristics of the complex, multidimensional GALEX dataset and are included with each data release as pipeline products. A description of key products is provided here for reference.

The corrected photon data are binned into images and flux calibrated in order to form the basis for the GALEX

¹² The notation derives from the ends of the delay line "A" and "C", or sometimes "START" and "STOP" in other work, thus the position is proportional to a timing difference of $A - C$ or "AmC."

¹³ The process will run with FUV-only data, although owing to the generally decreased numbers and brightnesses of stars in FUV data, some parameters such as the interpolation interval need to be adjusted.

¹⁴ Occasionally, matches to known stars cannot be found, usually due to pointing errors. In these rare cases, a good Point Spread Function (PSF) is achieved by performing the aspect refinement relative to *any* sources of emission detected in the field that are reasonably compact. This is called relative aspect refinement mode and results in images with good PSFs but poor absolute astrometry. Roll is not refined in relative mode.

catalogs. Count images (*-cnt*), which contain aspect-corrected detector counts per sky pixel are scaled by the effective area and exposure time to form the flux-calibrated intensity (*-int*) images. This step is accomplished with the relative response (*-rr*) image, which contains the effective exposure for each pixel:

$$rr(X, Y) = \sum_{t=0}^T flat(X(t), Y(t)) \times (1 - f_{dead}(t)) \times dt(t),$$

where $flat(X(t), Y(t))$ is the detector flat field¹⁵ shifted to properly align with the dithered image time slice, f_{dead} is the global electronic dead time based on the measured STIM pulser rate during each time slice,¹⁶ and $dt(t)$ is the fraction of each 1 s time slice during which data was collected (i.e. HV was on and the detector was otherwise in a nominal observing mode). Building the effective exposure time in this way properly handles the fact that the edges of the image receive less exposure than the middle, and that the sources each sample a 1' region on the flat field. The high resolution relative response image (*-rrhr*), which properly matches the count and intensity map pixel scales, is up-sampled from the 6'' relative response array. The intensity image is simply the count image divided by the high resolution relative response image.

As a final step, the background in each intensity image must be estimated and removed. Since the GALEX detectors have negligible intrinsic background and the UV sky is dark, estimation of the true background is not properly handled by the code within SExtractor. Instead, we create a custom threshold image for SExtractor that allows a bypass of the normal process for distinguishing low rate sources from background. The typical sky background count rates in high Galactic latitude GALEX pointings are $\sim 10^{-4}$ ($\sim 10^{-3}$) photons-s⁻¹-arcsec⁻² in the FUV (NUV), thus it is necessary to use the full Poisson distribution. The background is determined in a set of large bins, 192'' on a side. In images with exposure times greater than 10,000 s, the bins are 96'' on a side. For the Poisson distribution, the probability of observing greater than or equal to k events for a mean rate x is given by the incomplete gamma function $P_k(x)$ (Press et al. 1992). The average is computed iteratively within each background bin by clipping out high pixels where $P_k(x) < 1.35 \times 10^{-3}$, a probability equivalent to 3σ for a Gaussian distribution. Even after clipping, bright or extended sources can still bias the background determination, therefore, a 5×5 median filter is applied to the background bins. The resulting background values are linearly interpolated to the full resolution of the images. We have determined that the background may be biased by a few percent due to contamination from the wings of objects. To address this problem, background estimation and source extraction software is run twice on each GALEX image. The second run uses source position data from the first iteration to mask out source pixels and recompute the sky background and

background-subtracted intensity images. The resulting background image (*-skybg*) is subtracted from the intensity image to form the background-subtracted intensity image (*-intbgsb*), which is the image scanned by SExtractor.

There remain issues with the background at the 5% level that affect the MIS survey at the faint end. Furthermore, there are numerous artifacts not removed by the current pipeline that the user should be alert for. These include: bright star glints in the NUV images near the edge of the detector window; large out-of-focus pupil images resulting from reflections in the imaging window and dichroic beam splitter; a 1' diameter skirt around bright NUV sources (at the few-percent level in total energy) resulting from the proximity-focused photocathode; and photoemission and diffraction from the quantum-efficiency (QE) enhancing grid wires on the FUV detector window that appear as linear features around bright sources. Work is being done to flag and remove these features automatically in the pipeline software, but at present they amount to a small fraction of the survey coverage area ($\sim 1\%$).

The primary pipeline image products and descriptions are listed in Tab. 6, while catalog products are listed in Tab. 3. All of the catalog output products are generated by SExtractor, with the exception of the very useful merged catalog (*-mcat*), which combines FUV and NUV data in one table and adds derived columns including the detector coordinates of a source, detector intrinsic pulse height, number and brightness of nearby neighbors to a source, and many more. Matches between the bands are made by assigning a match probability to each pair of sources using the source separations and positional uncertainties. Sources with signal-to-noise (S/N) ratio of less than 2 or a separation greater than 3'' are not matched across bands (but do appear in the merged catalog). GALEX fields are uncrowded enough that the probability of a mis-match is very small, however a multiple candidate chain technique is used to assure that candidates are always matched the same way regardless of the order in which the process is started.

The GALEX data products are made available to the general public through the GALEX Science Database at MAST. A dedicated website provides access to the pipeline output files via a web-based browser, as well as other derived products, such as JPEG images. The catalog data are also stored in a commercial SQL Server database engine fine-tuned for astronomy applications, which provides sophisticated query interfaces supporting, for example, efficient spatial and color searches. The GALEX MAST database also contains enhancements over the photometric pipeline outputs, e.g. spatial cross-matching to the Sloan Digital Sky Survey (SDSS) catalog. Also, since adjacent GALEX fields overlap slightly, a *primary resolution* algorithm deals with the problem of unique sample selection. The formal GALEX footprint definitions of the GALEX surveys are published in the National Virtual Observatory's online Footprint Service (Budavari et al. 2006). On this site,¹⁷ one can not only search and visualize the GALEX sky coverage but also compute the exact area in square degrees or intersect it with other surveys.

¹⁵ The flat field has a value of 1 in regions for which a zero-point-magnitude source generates exactly 1 deadtime-corrected photon-s⁻¹.

¹⁶ Since the electronic STIM pulses occur at a precisely known rate, the fraction that are missing from the event list over a given interval will be known. This is the fractional dead time, which corrects the global rates only and does not account for local MCP saturation.

-sexcols	Listing of SExtractor catalog column names
-sexparams	Listing of SExtractor parameters used

4. PHOTOMETRY

4.1. GALEX Magnitude Reference System

The GALEX photometric calibration is tied to the *Hubble Space Telescope* (HST) through reference spectra supplied in the CALSPEC database and described by Bohlin et al. (2001). Almost all of the white dwarfs in this database are too bright for a photon counting instrument such as GALEX in direct imaging mode. As such, we are restricted to the dimmest sources in the catalog, which are all ultimately based on the *International Ultraviolet Observer* (IUE) calibration. All of these data have been reprocessed for the HST calibration program, as detailed in Bohlin (1996). The GALEX calibration is thus traceable to a hydrogen white dwarf model scaled using the ground based photometry of (Landolt 1992) in combination with several white dwarf transfer standards measured with the HST Faint Object Spectrograph. The combination of models and measurements was used to define corrections to the IUE calibration, thus transferring the HST calibration and allowing a fairly large group of standards from the IUE library to enter the CALSPEC database. Of these, we have observed 18 as detailed in Tab. 4, however we use one of the dimmest, LDS749b, as our primary standard for direct imaging. For the most part this white dwarf is in the linear range of the GALEX detectors – bright enough for high S/N measurements in just a few minutes, but dim enough not to saturate the microchannel plates. At the edge of the field in the NUV, where the detector gain is lowest, we apply a $\sim 20\%$ correction for local saturation. This effect was discovered relatively recently as our database of white dwarf observations has expanded to include a much finer sampling of the detectors in regions where the gain is an issue.¹⁸ At the time of this writing we are planning observations of the (dimmest) CALSPEC white dwarf, LB227, in order to improve our confidence in the NUV zero point. Unfortunately this source is not much dimmer than LDS749b, but since we believe the saturation of LDS749b is mild it should provide very useful verification of our saturation correction.

¹⁸ Since the detector MCPs are clamped at the edges, there is less chance for a charge packet at the edge of the field to spread laterally while traversing the stack. At the detector center, where there are small gaps between the plates, charge can spread across the pores. Thus the edges of the detectors tend to saturate more quickly than the centers. This effect can be seen for bright objects with multiple measurements by plotting the observed magnitude against the unsaturated detector pulse height, $\#_{UV-Q}$, tabulated in the merged catalog for each source. This quantity is the *normal* unsaturated pulse height of the detector at the location the source was measured. Note that the effect is minimized for large measuring apertures because the core of the PSF is primarily affected.

4.2. Magnitude Zero Point

GALEX uses the AB magnitude system of Oke and Gunn (1983) with the FUV and NUV magnitudes defined as follows:

$$m_{UV} = m0_{UV} - 2.5 \log f_{UV}$$

Here, f_{UV} is the dead-time-corrected count rate for a given source *divided by the flat field map*, which has a median value of order 0.85, and $m0_{UV}$ is the zero point that corresponds to the AB magnitude of a 1 count-s⁻¹ (cps) flat-field-corrected detection. There are independent relative response functions, and the zero points are:

$$m0_{FUV} = 18.82 \quad (3)$$

$$m0_{NUV} = 20.08. \quad (4)$$

The GALEX project has maintained these zero points constant; they are based on the imaging-mode bandpass determined during ground calibration. Improvements in calibration have been incorporated by adjusting the flat field, which is a stacked sky background image modified by an interpolated grid of white dwarf measurements. Since GALEX has a large field of view, this has the effect of moving the positions in the field of view for which sources with zero point magnitudes correspond to a true 1 count-s⁻¹ at the detector. For the most part this is not a major consequence since the flat field peak-to-valley variations for most of the useful field amount to about a factor of 2 even in FUV, and just 15% in NUV. There is thus only a modest effect on the estimation of the true expected noise for a given source with field position. In order to estimate any systematics resulting from application of the new flat field, a large sample of sources common to both the GR1 and GR2/GR3 releases have been compared. We find that *on average* sources in GR2/GR3 are shifted 0.04 and 0.01 m_{AB} fainter in FUV and NUV, respectively, compared to GR1. One must of course be careful applying these figures to any individual measurement because the flat has changed shape as well as its average value.

We have measured a drift in GR2/GR3 photometry of 0.003 ± 0.001 mag-year⁻¹ FUV and 0.016 ± 0.0005 mag-year⁻¹ NUV. This was identified with two independent means. In the first method (yielding the quoted results), we compared the GR2/GR3 photometry of 197 FUV and 547 NUV deep field sources between magnitudes 15 and 20 measured at approximately yearly intervals over the course of the mission. We have checked this result against the LDS749b white dwarf data, however this second result required considerable reprocessing. By design, the GR2/GR3 sample of white dwarf measurements through 2005 shows no drift. Each measurement was given equal

^aMagnitudes shown are predictions based on the GALEX bandpass and publicly available reference spectra from the *HST* CALSPEC database at <http://www.stsci.edu/instruments/observatory/cds/calspec.html>.

^bCoordinates are GALEX-measured in the NUV. One exception is BD+33°2642, which was only observed in grism mode; the coordinate provided is from Bohlin et al. (2001).

^cThis white dwarf is the primary GALEX standard.

footing in order to improve the spatial sampling, which only included 20 measurements per year early in the mission. In 2005, we identified the NUV white dwarf saturation effect in low gain areas, and also recovered the FUV detector from a major anomaly. In light of these circumstances, we implemented an extensive recalibration campaign. Over 1500 NUV measurements were added, but only 137 in the FUV because the detector was still completing its recovery. Thus the GR2/GR3 flat, generated with all of the white dwarf samples from the mission through 2005, is biased to 2005 in both bands and very strongly so in NUV. However, areas of the flat field sampled only in, say, 2003, will reflect the proper calibration for that epoch, which means that there is an additional systematic built into the flats for isolated areas. To address the drift, we reprocessed all of the GALEX LDS749b white dwarf data using a new flat field based on a grid of 165 LDS749b field measurements made over 2 days in 2006. We used a nearby field star of moderate NUV count rate rather than the bright LDS749b to generate the NUV flat (for FUV we used the white dwarf), mitigating concerns about the NUV saturation. The results of the white dwarf and deep field analyses are consistent with each other and are presented together in Fig. 3. The data are consistent with a linear drift (although less certain in the FUV band). We define the time of zero correction to be at eclipse 12000 based on the weight of that epoch in generating the GR2/GR3 flats.

We have not included an FUV LDS749b data point for 2005 in Fig. 3. This is because of a second issue we discovered during this analysis, which is that the 2005 FUV white dwarf data reads bright by about 5% when reprocessed with the 2006 single-epoch flat field. This is a result of the way the measurements were made in

FIG. 3.— The measured photometric drift for deep field sources between magnitudes 15 and 20 over the course of the GALEX mission. FUV data is shown in blue: diamonds for the deep field sources and circles for LDS749b. NUV data is shown in red: triangles for the deep field sources and circles for LDS749b. The deep field data shown represent the mean binned in 1000 eclipse segments. The drift is defined to be zero at eclipse 12000, which occurred in summer 2005 during the extensive white dwarf observing campaign upon which the current calibration is mostly based. It is not clear if the trend is due to contamination in the instrument, or due to a mild global gain decrease (fatigue) in the detector microchannel plates.

2005 while the FUV detector was completing its recovery from an anomaly. During that period (approximately a month), the detector was being cycled on and off for only very short observation periods (\sim minutes) while its stability was being tested. Since the detector was ramped to high voltage literally minutes before the observation began, it was still warming up during the observations, offsetting the calibration slightly. This means that there is a field-dependent systematic built into the GR2/GR3 FUV flat field of approximately 5% in the sense that

FIG. 4.— GALEX photometric “curve of growth,” which shows the median magnitude offsets relative to the largest aperture used for the white dwarf LDS749b. NUV measurements have been restricted to high pulse height areas of the detector to minimize any effect due to saturation.

most (about 77%) objects are actually brighter in the FUV than they appear. NUV is unaffected.

We have not determined if the observed drift is due to contamination or a global MCP fatigue. Since the performance of each MCP pore is sensitive to its total exposure, We would expect fatigue to affect NUV more since it typically detects photons at about 10 times the FUV rate. Furthermore, contamination would normally be expected to preferentially affect the FUV band. On the other hand, the effect we observe appears to affect bright and dim objects the same. Whichever effect is at play, we expect to apply a correction automatically in the pipeline during a future calibration update, however it is not accounted for in GR2/GR3.

4.3. Relative precision

For accurate and repeatable measurements of unresolved sources, aperture magnitudes are usually best since they are fixed from measurement to measurement. One needs to take care to choose an appropriate aperture for the task at hand. Smaller apertures are more useful for unresolved sources, but larger ones become desirable, even for point sources, when comparing the photometry of objects measured at the center and edge of the field (where the PSF is degraded), or for bright objects that have saturated cores. For the purposes of this paper, the SExtractor MAG_APER_4 magnitude is used unless otherwise noted. This 12" diameter aperture is a good compromise between the very large apertures required to gather almost all of the GALEX flux in the extended PSF (as is done for the white dwarf calibration) and the small ones that are optimal for minimizing the contribution of background. The relationship between the various standard SExtractor aperture magnitudes and the large tailor-made apertures used for white dwarf calibration are presented in Fig. 4.

In the GR2/GR3 release, the scatter in white dwarf measurements has been reduced to about 0.02 mag RMS in NUV and 0.045 mag RMS in FUV. This compares to a scatter of order 0.1 mag in both bands for the GR1 release. We attribute the improvement in precision to the way the flat field has been generated, using white dwarf measurements to modify the flat locally rather than using the average to scale a sky background field. As with

any instrument, care should be taken when interpreting the magnitudes of objects expected to have significantly biased spectral content compared to the white dwarf. These may have more scatter due to optical effects across the field of view.

We have also verified the performance of the flat field by means independent of the partially saturated (in the NUV) white dwarf standard. For this purpose, we have examined the sample of data from the DIS described in Section 4.2. This comprises a series of fields with several dozen full-eclipse-length observations, many at different roll angles (thus sampling multiple detector locations with the same source). By matching compact ($\leq 10''$ FWHM) sources with no neighbors closer than $12''$ in the co-added catalogs to the individual visit catalogs, a visit database of sources and magnitude errors (with the co-added catalog considered to be the truth catalog) has been generated. A comparison of high and low gain detector measurements for a given source reveals the count rate required to cause local saturation. For both detectors, the onset of saturation is at approximately $m_{AB} \sim 15$ (corresponding to 34 counts-s^{-1} FUV and $108 \text{ counts-s}^{-1}$ NUV) in the lowest gain regions of the detector. We thus restrict further analysis in this Section to the range $15 \leq m_{AB} \leq 17$.

With the unsaturated magnitude range determined over the whole field, we can proceed to compute the photometric repeatability as shown in Fig. 5. Here, we present histograms of the $12''$ -diameter aperture magnitude errors in each band. The Poisson error associated with each detection is of order 0.5% to 1.5%, while the total scatter we measure in the bright deep field sources is $\pm 0.05 m_{AB}$ RMS in FUV and $\pm 0.03 m_{AB}$ RMS in NUV. These figures agree well with the white dwarf results, thus concerns about the (mild) LDS749b NUV saturation correction are reduced. If the white dwarf saturation had not been properly accounted for, the flat field would have been adversely affected in the NUV low gain areas, which would in turn increase the photometric scatter of dimmer (definitely unsaturated) deep field sources in those same regions, and thus we would not expect good agreement in the scatter between the white dwarf and deep field samples.

The deep field *visit* magnitude errors are also presented as a function of the co-added “truth” magnitude in Fig. 6, which serves to illustrate an interesting bias effect on the faint end of the 1500 s depth MIS. Here, the predicted 3σ errors (including the flat-field-limited values derived for bright sources) are overplotted, showing good agreement with most of the observed distribution but failing on the faint end. This effect is similar in magnitude but opposite in direction for each detector. In the FUV, sources are detected in the co-added image that are not detected in the visit images except when the Poisson errors tilt the detection to the bright side (the Eddington bias), thus faint FUV detections are biased bright by about $0.1 m_{AB}$ compared to the “truth” catalog. Similarly in the NUV, more sources are detected in the co-added image, however the effect of the undetected sources is to force an overestimate of the NUV background of about 5% (with large scatter). In this case, faint NUV detections are biased *dimmer* by about $0.1 m_{AB}$ compared to the “truth” catalog. In each panel, solid overplotted lines show the median of the magnitude errors in each magnitude bin,

FIG. 5.— GALEX photometric precision as determined by repeated measurements of bright but unsaturated sources in the GALEX deep fields. These measurements are in good agreement with the results determined directly from repeat measurements of the white dwarf calibrators.

while dot-dash lines show the same quantity after the visit magnitudes have been re-computed using the co-add background estimation. This correction is indistinguishable from the solid line median in the FUV panel because the background is negligible, but completely cancels the faint end bias in the NUV. Since the effects of these two biases are in opposite directions for each band, they have a more significant effect on the UV color, about $0.2 m_{AB}$ at the faint end of the distribution.

For completeness, we present a similar analysis of the photometric errors in the 100 s AIS sample relative to cross-matched sources in overlapping MIS fields. As illustrated in Fig. 7, we find that the AIS magnitudes are biased bright at the faint end relative to the MIS for *both* detectors, and that corrections to the AIS magnitudes using MIS backgrounds have no effect at all. This result stems from the shallower depth of the AIS survey, which is source rather than background-limited.

4.4. Linearity

There are two sources of photometric non-linearity in the instrument: global non-linearity resulting from the finite period required for the electronics to assemble photon lists (during which time new events are locked out), and local non-linearity resulting from the MCP-limited current supply to small regions around a bright sources. The local effect complicates the NUV white dwarf calibration measurements.

Global effects are easily measured using the on-board “STIM” pulser, which electronically stimulates each detector anode with a steady, low rate stream of electronic pulses. These are resolved as point sources in the corners of the dose (*-scdose*) images. Since the real rate of STIM pulses is accurately known, the measured rate is used by the pipeline to scale the effective exposure. The count rates for all sources in the field are simultaneously

corrected. This effect is typically about 10% in NUV and a few percent in FUV, however it can become quite significant ($\sim 50\%$) for the brightest fields.

Local non-linearity can not be corrected well with the existing calibration. It affects not only the measured count rate of an individual bright source but also the source shape and position. Furthermore, the effects vary around the field of view with the gain of the detector (as exemplified by the white dwarf saturation correction described in Section 4.1). We have used standard stars to estimate the local non-linearity in each band as shown in Fig. 8. This data may be used to approximately correct bright sources that are within the measured range. Note that the measurements presented in the Figure are for $34.5''$ (APER.7) and $3'$ diameter apertures; the effect will be much *worse* when small apertures are used. The NUV detector is more robust to bright sources because its photoelectrons are proximity-focused and thus present a larger source image (with lower count density) to the MCP. Local photometric non-linearity is strongly source-size dependent. The saturation shown in Fig. 8 is a worst-case scenario (using stars). Wide scatter in measurements of bright sources is an indication of the variation of the onset of saturation at different detector locations.

We have increased the local count rate limit to 30,000 cps per source in NUV, which corresponds to approximately 9th magnitude. This new limit allows most of the sky to be observed. The FUV local limit is maintained at 5,000 counts-s $^{-1}$, which is not currently a survey constraint. Global detector limits are set in hardware (rather than the planning system) to 100,000 counts-s $^{-1}$, a limitation based largely on the boundaries of ground testing and engineering judgment about safe rates of gas generation inside the sealed detector tubes. Areas such as the galactic plane and the Magellanic Clouds are still restricted by the 100,000 cps global limit

4.5. The GALEX Deep Fields

The specific case of faint DIS photometry presents its own special challenges. The relatively large GALEX PSF affects the photometry of faint sources, mostly due to source confusion (Xu et al. 2005). As an alternative to the GALEX pipeline for faint source extraction, a Bayesian approach has been attempted by others (Guillaume et al. 2006) to estimate the UV flux using prior information from external, well-resolved images (mostly from visible wavelengths). The basic idea is to generate an image with prior sources convolved with the GALEX PSF, and to estimate what scaling factors to apply that will best fit the UV image. The implemented method is based on a maximum likelihood parametric optimization in the presence of Poisson noise. Scaling factors were extracted via an iterative procedure to solve the set of non-linear equations based on the Expectation-Maximization (EM) method. In order to test the reliability of the photometry extracted using this method, simulated objects (with a large range of UV flux) were added to the GALEX DIS images. For an NUV DIS image with 60 ksec exposure, it was possible to recover the photometry of simulated sources with an accuracy of $0.3 m_{AB}$ to NUV ~ 25.5 , extending the faint-end limit of the survey by about a magnitude.

FIG. 6.— GALEX photometric repeatability as a function of magnitude as determined by repeated measurements of sources in the GALEX deep fields (with individual measurements of order 1000 s). In each panel, heavy dashed lines are the 3σ values that would be expected given the flat field precision and Poisson counting statistics, while the \times symbols show the actual value for each magnitude bin. Solid overplotted lines show the median of the magnitude errors in each magnitude bin, while dot-dash lines show the same quantity after the visit magnitudes have been re-computed using the co-add background estimation.

FIG. 7.— GALEX AIS photometric repeatability as a function of magnitude as determined by repeated measurements of sources in overlapping MIS fields. In each panel, heavy dashed lines are the 3σ values that would be expected given the flat field precision and Poisson counting statistics, while the \times symbols show the actual value for each magnitude bin. Solid overplotted lines show the median of the magnitude errors in each magnitude bin, while dot-dash lines show the same quantity after the visit magnitudes have been re-computed using the co-add background estimation (in the AIS this correction does not have a significant effect). At the very faint end, there is an apparent bias toward visit magnitudes brighter than co-added magnitudes due to Eddington bias in the source-limited sample.

5. RESOLUTION

There are numerous contributors to the width of the GALEX PSF, including the optics, detectors, and ground pipeline. The reconstruction algorithms for GR2/GR3 have improved to the point that the instrumental contributions are now the largest share, particularly in the proximity-focused NUV channel. As we will show, the GALEX detectors dominate in this area and have significantly position-dependent performance.

To verify the fundamental instrument performance from on-orbit data, some bright stars were analyzed individually, outside the pipeline. These results show per-

formance that is consistent with or better than what was measured during ground tests. We have also verified the end-to-end performance including the pipeline by stacking images of stars from the MIS survey that were observed at different locations on the detector. The results of these composites are shown in Figures 9 and 10. Performance is reasonably uniform except at the edge of the field, where it is significantly degraded. Some remaining degraded areas of the images may yet be improved with updates to the static calibration. Note that DIS surveys co-add data with many roll angles, so the DIS PSF is considerably more symmetrical across the field of view.

FIG. 8.— Measured count rate versus predicted count rate for the white dwarf standards measured to date by GALEX using 34.5'' (APER₇) and 3' diameter apertures. These measurements represent a worst case because they are for point sources. The non-linearity will be much *worse* when measuring fluxes using small apertures, since this effect is concentrated at the core of each image.

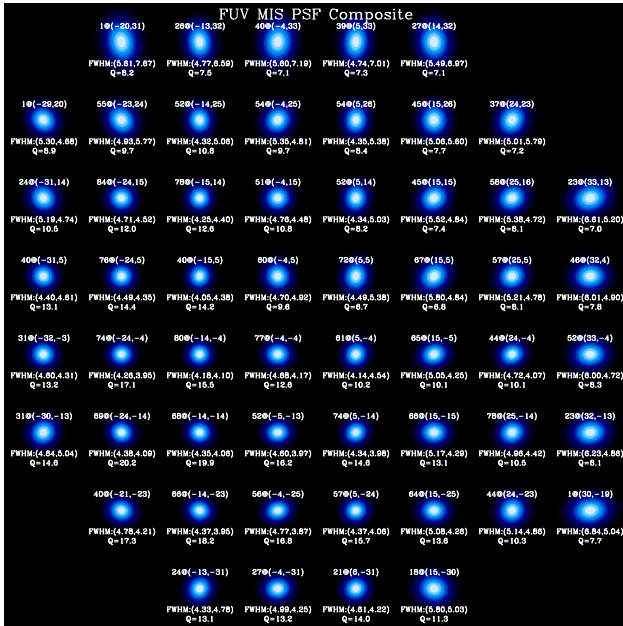

FIG. 9.— Composite PSFs for the GALEX FUV channel in detector coordinates. The individual images are exaggerated for clarity. Upper data values in the format $N@X,Y$, where N is the number of stacked images and (X,Y) is the position in minutes of arc from the field center. The FWHM is specified in seconds of arc for each detector axis. Q is the typical pulse height at the specified detector location, in bins. The pulse height scale is not extremely well calibrated, but it is linear with 10 bins $\sim 1 \times 10^7$ electrons).

Many of the regions with degraded resolution correlate with low detector gain, an effect illustrated in Fig. 11. The relative detector gain (or charge, 'Q') in the region of measurement for each source is tabulated in the merged catalog. This gain measurement is obtained from a look-up table that represents the detector in an unsaturated condition. The *actual* gain measured during the observation is available in the pulse height (-scq) image data product.

It is also evident that the GALEX PSF has structure a significant distance from the center. We have character-

FIG. 10.— Composite PSFs for the GALEX NUV channel in detector coordinates. The individual images are exaggerated for clarity. Upper data values are $N@X,Y$, where N is the number of stacked images and (X,Y) is the position in minutes of arc from the field center. The FWHM is specified in seconds of arc for each detector axis. Q is the typical pulse height at the specified detector location, in bins. The pulse height scale is not extremely well calibrated, but it is linear with 10 bins $\sim 1 \times 10^7$ electrons).

FIG. 11.— The full width at half maximum of the GALEX PSF based on composite images for each detector as a function of *intrinsic* detector pulse height. In general, low pulse height regions are near the edge of the detector.

ized this by building a composite PSF of the white dwarf calibrator LDS749b as shown in Fig. 12. The effects of local non-linearity are also illustrated here by the highly saturated white dwarf HZ 44, the brightest we have observed with GALEX in imaging mode. The effect of the saturation is strongest in the core of the PSF, causing the wings to be strongly emphasized.

6. ASTROMETRY

The GALEX GR2/GR3 astrometric precision represents an improvement of order 20% over GR1 (and much more compared to the Early Data Release). The dynamic pipeline transformation is generally not a limiting factor

FIG. 12.— GALEX FUV and NUV composite encircled energy curves for two white dwarf standards. A composite of LDS749b measurements forms the unsaturated (solid) curve, while the brightest standard that we have observed, HZ 44, defines the saturated curve. The reference count rates for the saturated curves are the predicted values; measured rates are much lower as indicated by the low encircled energy values.

as it had been in earlier releases. The static transformation (primarily the distortion map) is also performing very well for most of the field of view. Improvements could still be made that would not only improve the global astrometric precision but also the point spread function (PSF) at the edge of the field.

The distortion maps for the GR2/GR3 calibration are the result of several flight-based iterations on the pre-flight calibration. The first, which was implemented for the GR1 data release, used Tycho-2 catalog (Hog et al. 2000) reference stars to refine the distortion map for each detector independently. An iterative technique was used until the measured GALEX positions converged with the reference positions, a technique that relied on the assumption that the distortion across a $\sim 1'$ (~ 1 mm) region of the detector (the footprint of the dither pattern) is reasonably represented by a single average value. This technique worked well, however there were relatively few FUV stars available to perform the analysis (a few thousand). The FUV-NUV relative astrometry retained some noticeable ($\sim 1''$) misalignments. We have addressed this issue with cross-matched SDSS data. Since the SDSS astrometry is better than $0.1''$ RMS (Pier et al. 2003), it can be regarded as essentially perfect for our purposes. The sample we gathered contains 69642 objects spectroscopically classified as quasars (SDSS SPECCLASS = 3, a convenient point source sample compiled for other applications). Objects were considered matches if they fell within $2.5''$ of each other. There was no discrimination based on location in the GALEX field of view. We binned these results into a relatively coarse grid ($\sim 1'$), the intent of which was to “stretch” the existing plate solution to remove low spatial frequency errors. The result of this improvement is that the GR2/GR3 absolute astrometric precision achieved by the GALEX MIS within 0.6° of the field center for bright (signal-to-noise ratio ≥ 10) point sources is $0.49''$ RMS in the NUV and $0.59''$ RMS in the FUV, with similar relative precision between the two bands.

In Fig. 13 we present histograms of the position errors

FIG. 13.— Distribution of absolute astrometric errors in the GALEX GR2/GR3 survey data for quasars with $S/N \geq 10$ in each band matched against the SDSS.

FIG. 14.— FUV GR2/GR3 MIS absolute astrometric performance for field center and field edge distributions of SDSS quasars with GALEX $S/N \geq 10$

for high S/N SDSS quasars detected by GALEX. The most noticeable image defect resulting from the current astrometric solution is the degraded PSF at the edge of the field. As shown in Figures 14 and 15, the astrometric precision in the outer $5'$ of the detector, while degraded, still performs nearly at the level of the central $30'$. Generally speaking, matches between GALEX and other surveys can be safely performed with a $2''$ window as indicated by Fig. 16.

The most promising future improvement to the astrometric calibration probably involves a new pipeline module that would scale the amplitude of the distortion maps by a factor determined from measurements of the STIM pulses at the corners of each image. Much of the necessary data to eliminate this “breathing” mode is already available. Another more complex possibility involves re-processing the reference star data in ~ 20 s intervals to reduce the footprint of each source sample on the detector and thus more finely sample the detector grid. Such an analysis would be most useful near the edge of the detector where the distortion map is changing rapidly.

7. SPECTROSCOPY

The spectroscopic mode utilizes a CaF_2 grism (a prism with a ruled surface) that can be moved into the converging beam of the telescope to form simultaneous (slitless)

FIG. 15.— NUV GR2/GR3 MIS absolute astrometric performance for field center and field edge distributions of SDSS quasars with GALEX $S/N \geq 10$

FIG. 16.— The percentage of GALEX-SDSS matches as a function of matching radius. An MIS sample with $S/N \geq 10$ and field radius less than 0.6° was used for this analysis. Note that the matched sample is limited to $2.5''$ maximum error, although based on the shape of the distribution this does not appear to be an issue.

spectra of all sources in the field in both bands. Many spectra will normally overlap, a problem addressed by rotating the grism on its axis to different position angles during repeat observations of the same field. Each spectrum has an “undeviated wavelength point” around which it will rotate as the grism position angle is changed (thus any given spectrum will have an optimal set of grism position angles depending on the location of nearby sources). As the position angle changes, the undeviated wavelength point remains fixed in the field as illustrated by Fig. 17. The resulting spectra can be combined to eliminate confusion. The standard GALEX spectroscopy pipeline is designed for isolated point sources, which are detected in the GALEX direct image observations. Extended or overlapping sources, or sources which do not appear in the direct image catalog require a special pipeline reduction with modified parameters.

A relative position correction as a function of time is applied to the spectral image data using a technique very similar to that used for direct image photons. Using the brightest sources from the catalog, an aspect correction is applied to the entire exposure by fitting four parameters: shift in dispersion direction, shift in spatial direction, spacecraft roll angle, and grism position angle.

FIG. 17.— A composite image of GALEX grism spectra collected with multiple grism position angles. As the grism is rotated in its mount, each spectrum spins around its own undeviated wavelength point to form a “pinwheel” in the composite, illustrating the optimal grism angle (producing an unconfused spectrum) for each source.

A spectrum points North (blue to red) when the grism position angle is 0° and towards the East when it is 90° .

Bright sources may show grism orders ranging from -4 to $+5$ across the field, however only two orders in each band are typically extracted. For NUV, the highest response is in first order with a total system peak response of 40 cm^2 . For FUV, the strongest order is 2nd with a peak response of 20 cm^2 . The dispersion angles γ_{FUV} and γ_{NUV} in arcseconds from the undeviated wavelength point for FUV 2nd order and NUV 1st order are given by:

$$\gamma_{FUV} = -4530.7 + 7.3859\lambda - 3.9254 \times 10^{-3}\lambda^2 + 7.4750 \times 10^{-7}\lambda^3$$

$$\gamma_{NUV} = -882.1 + 7.936 \times 10^{-1}\lambda - 2.038 \times 10^{-4}\lambda^2 + 2.456 \times 10^{-8}\lambda^3$$

where λ is the wavelength in Angstroms, accurate to a few tenths of an arcsecond.

Using the catalog positions, image strips (aligned to the dispersion direction) are created for each source using the corrected photon positions. Fig. 18 shows how a portion of the field image translates into a dispersion-aligned image strip for each band. The Figure shows image strips covering 1700 arcseconds in the dispersion direction to illustrate the weaker orders. Only 900 arcseconds (from -100 to $+800$ arcseconds relative to the undeviated point) covering the two strongest orders in each band are stored during actual data reductions. The width of each image strip is 78 arcseconds. Fig. 18 also shows the undeviated point in each image strip (marked with an \times) which occurs at about 1700 \AA in 1st order in both bands. This is the point where the spectral images for all position angles intersect.

The spectral shape, strength, and position of neighboring sources are estimated from the direct image catalog and are masked from each image strip. Additional masking is done on each strip when the exposures are coadded to eliminate other artifacts not predicted by known neighboring sources, which may be due to reflections,

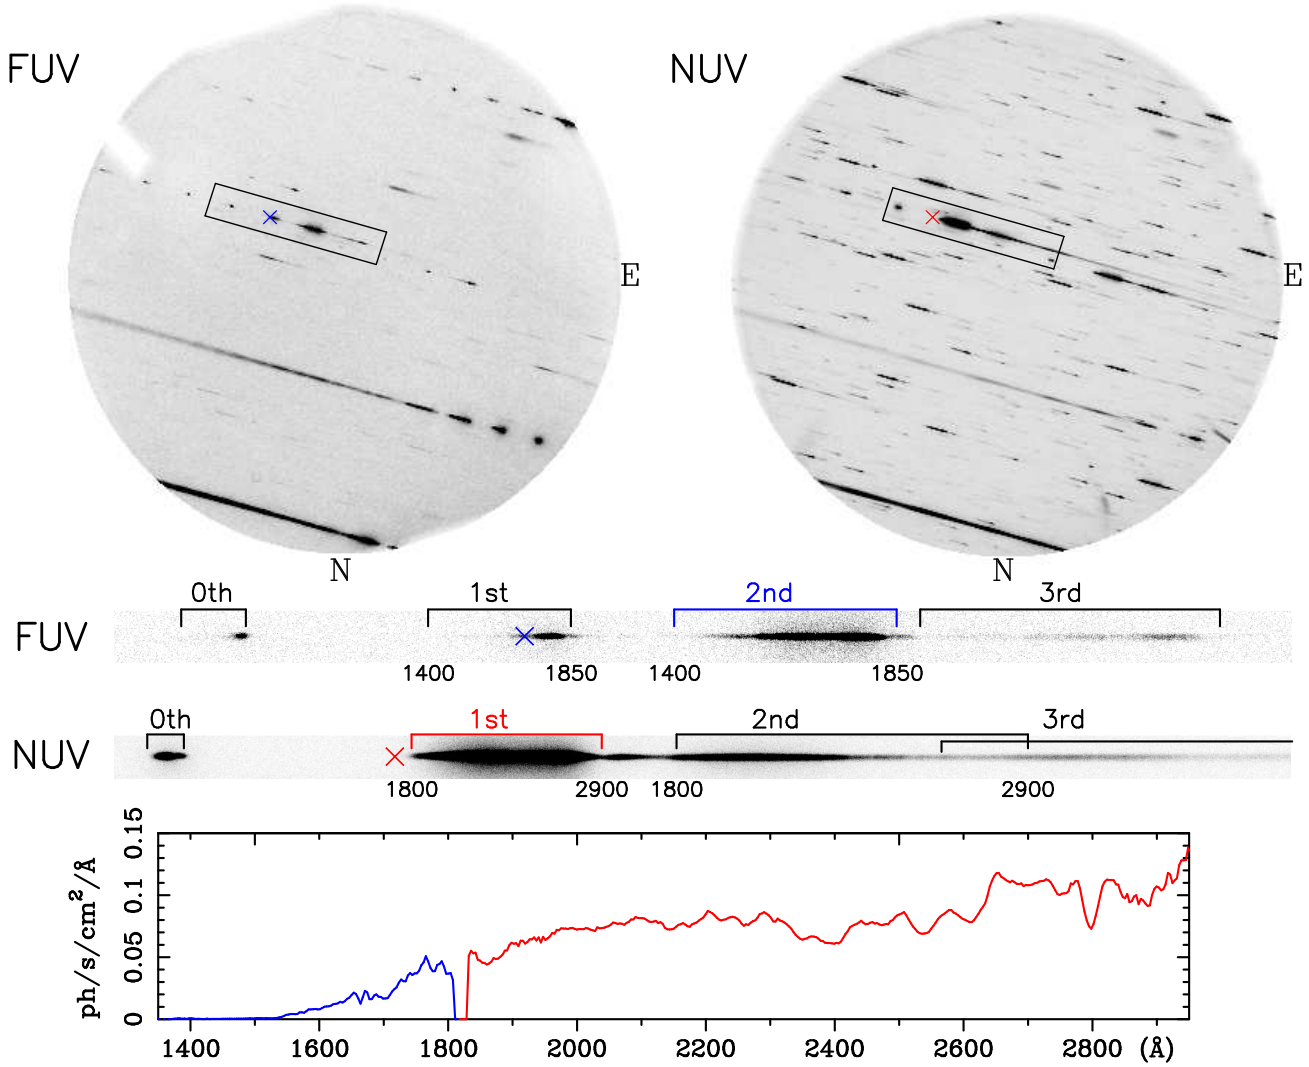

FIG. 18.— Example bright object GALEX spectra. Circular images at top show the reconstructed FUV and NUV spectral image data. A rectangular region of interest identifies the same spectrum in each band, while an \times marks the undeviated wavelength point around which the spectra would spin if the grism were rotated. The rectangular regions are enlarged and annotated in the middle of the frame, where wavelength ranges and spectral orders are identified. In the bottom panel, the calibrated spectrum is shown in blue for the FUV portion and red for the NUV portion.

ghosts, hot spots, or unidentified sources near the edge of the field. The response map is then applied and the background is fit and subtracted at each wavelength point. An aperture extraction (summation) is computed for the primary spectrum using the brightest order in each band (NUV 1st and FUV 2nd). An optimal extraction is also computed using a PSF model. A 20 Angstrom region is set to zero in the spectrum at around 1820 Å indicating the separation between FUV and NUV.

A list of sources for which spectra will be extracted is determined by estimating what the final S/N of a given source will be after coadding all grism observations. Any source which will achieve a S/N per resolution element in the coadded result of ≥ 2 in FUV or ≥ 3 in NUV is selected for spectral extraction. For multi-exposure data reductions, the masked image-strip photon and response data are coadded for each source. For both individual and coadded spectra, a response correction is applied as a function of wavelength and the spectra are rebinned to a linear scale. The primary (NUV 1st order and FUV 2nd order), secondary (NUV 2nd order and FUV 3rd order), and optimal (the primary spectrum with PSF weighting

TABLE 5
TYPICAL SIGNAL-TO-NOISE RATIO

SPECTRA AT MIS DEPTH
(1500 s).

m_{AB}	FUV S/N	NUV S/N
16	10.4	21.2
18	3.4	6.1
20	0.79	1.22
22	0.14	0.20

in the spatial direction) extractions are stored in 3 arrays in the final reduced data file. The estimated S/N for unresolved sources in single-orbit spectra is shown in Tab. 5.

The usable wavelength range is approximately 1300 to 1820 Å for FUV (2nd order) and 1820 to 3000 Å for NUV (1st order). The average dispersion is 1.64 and 4.04 Å per arcsecond for FUV (2nd order) and NUV (1st order), respectively. The average resolution ($\lambda/\Delta\lambda$) for a point

source (assuming a 5 arcsecond PSF) is about 200 (8\AA) and 118 (20\AA) for FUV (2nd order) and NUV (1st order), respectively.

Although there is evidence that the response may vary with position on the detector or with the grism position angle, a single wavelength-dependent calibration is used for each band. These variations may introduce a calibration error of about 3% in the body of each spectral order and about 10% near the edges of each order.

8. CONCLUSIONS

We have described the GALEX performance and calibration results for the GR2 and GR3 data releases. These releases have identical pipeline calibrations that are significantly improved over the previous GR1 release. The analysis we have presented provides an overview of the data quality, errors and peculiarities that are likely to confront astronomers.

The relative photometric precision is 0.05 and 0.03 m_{AB} in the FUV and NUV respectively. We have identified several photometry issues that will be improved in future calibrations. The first is a systematic drift with time of order 1% in FUV and 6% in NUV, total, over the period of the released data (~ 4 years). The sense of the drift is that objects appear to be growing fainter with time. The second issue is that the current FUV calibration relies on data collected in a non-standard mode during the 2005 FUV recovery, and this data appears bright by 5% compared to other measurements of the same objects collected in the standard mode. The third issue is that the NUV zero point is defined by a white dwarf calibrator that is at least partially saturated. While we have evidence that the saturation is mild and correctable,

we are planning confidence-building observations of an additional white dwarf, the dimmest in the CALSPEC catalog, to help resolve the issue.

The astrometric precision has been improved, about 20%, to 0.5" RMS. There is evidence that it may be improved further by accounting for the detector "breathing" mode already measured with existing data from an external pulsar that runs in parallel during all detector operations.

All of our performance parameters continue to meet flight requirements. As the mission continues, we naturally expect the calibration to evolve. The instrument itself continues to function nominally in spite of a series of flight anomalies especially with the FUV detector. We have modified operations and flight software over the mission to respond to these issues. While some of them have significantly affected the FUV observation efficiency, none give any indication of affecting the instrument performance. We believe there is room to increase the count rate limits for both detectors (especially FUV), and to the extent possible we plan to explore higher rate fields closer to the Galactic plane after the primary surveys are completed.

GALEX (Galaxy Evolution Explorer) is a NASA Small Explorer, launched in April 2003. We gratefully acknowledge NASA's support for construction, operation, and science analysis for the GALEX mission, developed in cooperation with the Centre National d'Etudes Spatiales of France and the Korean Ministry of Science and Technology.

Facilities: GALEX

TABLE 6
A SUMMARY OF GALEX PIPELINE PRODUCT ARRAY CONTENT AND FORMAT.

Product	Extension	Format	Units	Scale	Description
Artifact Flags	-flags	480×480		$12''\text{-pixel}^{-1}$	Artifact flags for each pixel
Background-Subtracted Intensity	-intbgsb	3840×3840	counts-s^{-1}	$1.5''\text{-pixel}^{-1}$	Intensity-Sky Background
Count	-cnt	3840×3840	counts	$1.5''\text{-pixel}^{-1}$	Aspect-corrected image, no flat field.
Dose	-scdose	2250×2250	counts	$3''\text{-pixel}^{-1}$	Detector space, corrected for walk, wiggle and distortion.
Exposure	-exp	960×960	s	$6''\text{-pixel}^{-1}$	Exposure, <i>uncorrected</i> for flat field or dead time
Intensity	-int	3840×3840	counts-s^{-1}	$1.5''\text{-pixel}^{-1}$	Count image divided by relative response image
Movie	-movie	480×480	counts	$12''\text{-pixel}^{-1}$	Count map slices at 16 s intervals
Object Mask	-objmask	3840×3840		$1.5''\text{-pixel}^{-1}$	Areas masked during sky background estimation
Pulse height	-scq	2250×2250	bins	$3''\text{-pixel}^{-1}$	Average pulse height per pixel
Relative response	-rrhr	3840×3840	s	$1.5''\text{-pixel}^{-1}$	Effective exposure, corrected for dither, flat field and dead time
Relative response	-rr	960×960	s	$6''\text{-pixel}^{-1}$	Effective exposure, corrected for dither, flat field and dead time
Sky Background	-skybg	3840×3840	counts-s^{-1}	$1.5''\text{-pixel}^{-1}$	Sky background estimate
Threshold	-wt	3840×3840		$1.5''\text{-pixel}^{-1}$	Background-subtracted intensity map divided by estimated Poisson noise
